ACKNOWLEDGEMENTS

Research for this project was sponsored by the Division of Remedial Action Projects, U.S. Department of Energy. The authors wish to acknowledge the support of J. E. Baublitz, Director, Division of Remedial Action Projects, E. G. DeLaney, Manager, FUSRAP/Surplus Facilities Group, A. J. Whitman, L. C. Brazley, and members of their staff. The authors recognize the valuable contributions of R. W. Doane, B. S. Ellis, J. B. Kark, J. L. Marley, S. V. Kaye, D. A. Roberts, J. A. Roberts, W. H. Shinpaugh, and D. A. Witt of the RASA group for participation in collection, analysis, and reporting of data at the site of the survey. In addition, the authors appreciate the manuscript preparation by S. E. Huckaba.

RESULTS OF THE SURVEY ACTIVITIES AND MOBILE
GAMMA SCANNING IN MONTICELLO, UTAH

C. A. Little

ABSTRACT

The town of Monticello, Utah, was once the site of an active mill which processed vanadium ore (1942-1948), and uranium ore (1948-1960). Properties in the vicinity of that mill have become contaminated with radioactive material from ore processing. The Radiological Survey Activities (RASA) group at Oak Ridge National Laboratory (ORNL) was requested by the division of Remedial Action Projects (DRAP) in the Department of Energy (DOE) to: (1) identify potentially contaminated properties; (2) assess natural background radiation levels; and (3) rapidly assess the magnitude, extent, and type (i.e. ore, tailings, etc.) of contamination present on these properties (if any). This survey was conducted by RASA during April 1983. In addition to the 114 properties previously identified from historical information, the ORNL mobile gamma scanning van located 36 new properties exhibiting anomalous gamma radiation levels. Onsite surveys were conducted on 145 of the 150 total properties identified either historically or with the gamma scanning van. Of these 145 properties, 122 of them appeared to have some type of contaminated material present on them; however, only 48 appeared to be contaminated to the extent where they were in excess of Environmental Protection Agency (EPA) criteria (40 CFR 192). Twenty-one other properties were recommended for additional investigation (indoor gamma scanning and radon daughter measurements); of these, only ten required further analysis.

This report provides the detailed data and analyses related to the radiological survey efforts performed by ORNL in Monticello, Utah.

* The survey was performed by members of the Radiological Survey Activities Group of the Health and Safety Research Division at Oak Ridge National Laboratory under DOE contract DE-AC05-84OR21400.

INTRODUCTION

The town of Monticello, Utah, was once the site of an active mill which processed vanadium ore from 1942 through 1948 and uranium ore thereafter until closing in 1960. Vicinity properties in the town have been the subject of radiological surveys conducted in 1971, 1980, and 1982. During those surveys, 114 properties were listed as having or being suspected of having "anomalous" levels of radioactive materials within their confines. Due to limited soil sampling during those surveys, the presence or absence of uranium mill tailings on these properties was neither confirmed nor denied.

During the period April 11-22, 1983, members of the Radiological Survey Activities (RASA) Group of Oak Ridge National Laboratory (ORNL) visited Monticello. The objectives of the radiological survey were threefold: first, to take soil and gamma exposure measurements at numerous locations within the confines of the community to ascertain the gamma exposure background and the nominal ^{226}Ra content of the soil; second, to confirm or deny the presence or absence of uranium mill tailings on the previously listed properties; and third, to determine whether or not additional properties in Monticello were contaminated by scanning all accessible streets with the mobile gamma scanning van.

SURVEY METHODS

BACKGROUND MEASUREMENTS

Background samples of soil and measurements of gamma exposure were taken at 30 locations throughout Monticello. The locations were chosen systematically by utilizing a city map. Sample locations were evenly spaced at about two blocks apart. The soil samples were taken at a depth of 0-15 cm from undisturbed soils or turf whenever possible. Properties suspected of being contaminated were avoided. Samples and measurements were taken at curbside locations or public property rather than on private property. The 30 locations of background samples are listed in Table 1.

Gamma exposure measurements were made using a Pressurized Ionization Chamber (PIC) certified accurate by the National Bureau of Standards (NBS). Measurements were made at a height of 1 m above the ground surface. An average of about 10 instantaneous measurements was taken to be the gamma exposure in $\mu\text{R}/\text{h}$ at that location. Measurements of the gamma exposure rate in counts per minute (cpm) were made at the same location using a hand-held scintillator.

WALK-ON SURVEY

The walk-on surveys conducted in Monticello were for the express purpose of confirming or denying the presence of uranium mill tailings on the property. The survey also had the previous information as supplied by Bendix Field Engineering Corporation (see Appendix I). For each property, this information included a picture of the property, a rough drawing of the boundaries and structures, and a gamma map from a previous survey.

Each property was completely gamma-scanned using hand-held gamma scintillators at the ground surface. The resulting regions of elevated radioactivity, if any, were drawn on the existing map of the property. If no map was available, a rough sketch of the property was drawn. The regions of contamination were compared with the extant gamma maps in an attempt to verify that no region had been missed.

Following complete gamma scanning of the property, samples were taken from the contaminated regions of the soil. Samples were taken at the location of highest gamma exposure rates. If necessary, a posthole digger was used for access to the contaminated region. Sampling pieces of uranium ore was avoided whenever possible since the presence of these ore pieces would not accurately reflect concentrations of radionuclides in soil. If more than one region of contamination was found on a property, several samples may have been taken. At least one sample was taken from each property. On uncontaminated properties, a soil sample was taken from the location of maximum gamma exposure since this sample would reflect the maximum concentration of radionuclides in soil present on that property.

Properties that exhibited unexpectedly high gamma exposures in building materials were so noted. If possible, a sample of the suspect building material was taken for analysis. Such samples were frequently unavailable.

MOBILE GAMMA SCANNING

The following is a brief description of the scanning methods utilized for the mobile scanning of the Monticello area. Details of the system description and operation are described elsewhere.¹

Instrumentation

The gamma radiation detection system employed in the ORNL scanning van consists of three 4 x 4 x 16-in. NaI(Tl) log crystals housed in a lead-shielded steel frame to provide a 12 x 16-in. detector surface area for acceptance of gamma radiation through one side of the survey van. The detector and shield height can be varied with a hydraulic lift mechanism to optimize the detector field-of-view. The detector output is transferred to a computer-controlled, eight-channel discriminator and interface, which provides for continuous analysis of data inputs for correlation of system location with count rate information. Six separate energy regions-of-interest are analyzed and a ²²⁶Ra-specific algorithm is employed to identify locations containing residual radium-bearing materials. Multichannel analysis capabilities are included in the system for additional qualitative radionuclide identification.

Mobile Scanning Methods

The data analysis method employed on the ORNL van is based on computations involving background count rates in specific energy regions. These background levels are normally obtained within small (10 square block) survey areas, based on coverage of at least 75% of the accessible streets in that area. Subsequent street-by-street scans of these areas are conducted at a slow speed (<5 mph), minimizing the distance between the detectors and the subject properties. All accessible streets, alleyways, and other public thoroughfares are scanned in both directions to maximize the number of views obtained for each property. Anomaly

locations are highlighted by the computer system when the preset hit criteria are exceeded during the scan.

LABORATORY ANALYSIS METHODS

Radiological Analysis

Samples collected for both background determination and from surveyed properties were analyzed for both ^{226}Ra and ^{238}U . Samples were dried at 110°C for 24 h, ground, placed in capped sample vials and weighed. Samples counted for ^{226}Ra on a high purity germanium semiconductor detection system coupled with a Nuclear Data Corporation ND 2400 gamma spectrometer. Details about the counting system, its operation, and specifications are given in section 15.1 of Reference 2. Samples were analyzed for ^{238}U by the Analytical Chemistry Division of ORNL. A 5 cm^3 aliquot of soil is subjected to a thermal neutron flux in the Oak Ridge Research Reactor, counted for ^{235}U and converted to concentration of ^{238}U . Details of this procedure are given in section 15.2 of Reference 2.

Elemental Analysis

Multi-elemental analysis was conducted for each property and background soil sample taken in Monticello. The samples were analyzed using an inductively coupled plasma optical emission spectrometry (ICP-OES) system.³ Samples were analyzed for concentrations of the following elements: aluminum, barium, beryllium, boron, calcium, cesium, chromium, cobalt, copper, iron, lanthanum, lead, lithium, magnesium, manganese, molybdenum, nickel, niobium, phosphorus, potassium, scandium, sodium, strontium, thorium, titanium, vanadium, zinc, and zirconium. Relative to results of the surveys conducted in Monticello, only two elements were of interest -- vanadium and copper; therefore, in this document, concentrations for only these two elements have been reported. These two elements (vanadium and copper) were the only elements which were found to be helpful in discriminating between material originating from the Dry Valley and Monticello mill sites.

CRITERIA FOR CONTAMINATION CLASSIFICATION

Three criteria were used to judge the extent of contamination or need for remedial action: (1) ^{226}Ra concentration in soil; (2) ^{238}U concentration in soil; and (3) areal extent of contamination in the soil. In addition, because the tailings in the Monticello region conceivably come from several sources (Monticello and Dry Valley mills) and several different processes (acid leach, carbonate leach, etc.) they are difficult to identify visually. Therefore, we instituted a criteria to separate tailings from ore when found in soil. This criteria and the three above will each be discussed briefly in the following sections. If remedial action is found to be required based on data within this report, the remedial action would be based on EPA's "Standards for Remedial Action at Inactive Uranium Processing Sites," 40 CFR 192, and not on site-specific health effect assessments.

RADIUM CONCENTRATION IN SOIL

Soil samples were analyzed for ^{226}Ra concentration in soil by the methods described above. A property was considered to be in violation of the radium criteria if it exceeded 5 pCi above background per dry gram of soil. This was the interim guideline for remedial action published by the U. S. Environmental Protection Agency (EPA) for surface soil at the time of the surveys (40 CFR 192.12). Because no augering was done during the soil sampling, and no samples were taken below 15 cm of depth, the more conservative 5 pCi/g guideline was applied rather than the less stringent 15 pCi/g standard for subsurface soils. Based on the background sampling done in Monticello, this means that any sample having ^{226}Ra in concentration equal to greater than 7.5 pCi/g would exceed the criterion. No attempt was made to apply statistical or probabilistic tests to the mean or any sample when comparing with the criterion.

URANIUM CONCENTRATION IN SOIL

Soil samples were also analyzed for ^{238}U in soil by the methods described above. A property was considered to exceed the ^{238}U criterion if it exceeded 75 pCi/g above background. This criterion is equivalent to the "soil remedial action guideline" suggested by the Department of Energy (DOE) for the Formerly Utilized Sites Remedial Action Program (FUSRAP).⁴ Again, the background sampling at Monticello imply that the ^{238}U criterion would be exceeded by a soil concentration of 77 pCi/g of dry soil. As before, no attempt was made to apply statistical tests to the mean or any sample when comparing with the criterion.

AREAL EXTENT OF CONTAMINATION

The areal extent of contamination criterion applied to the surveyed properties is 100 m². Any property which appeared to have a contaminated region exceeding this area, either in one contiguous region or several substantial subregions, was considered to be in excess of the criterion. This criterion is in concert with the distribution of contamination used to estimate health effects when developing the FUSRAP radiological guidelines.⁴ As with the ^{226}Ra and ^{238}U criteria, the areal extent criterion was considered to be deterministic rather than probabilistic.

TAILINGS IDENTIFICATION

As previously mentioned, the tailings found at Monticello represent several different sources and processes. The two potential sources of tailings include the Monticello mill which processed during its history for both uranium and vanadium, and the Dry Valley site which processed for vanadium alone. Anecdotal evidence indicates that residents of the region have had at some time, access to both sites and the tailings located at each. This varying of both source and process made visual identification of the tailings material difficult and unreliable.

Because suspected tailings could not be reliably identified visually, an arbitrary criterion was established to classify a property as being tailings-contaminated. Following completion of soil sample

analysis for both ^{226}Ra and ^{238}U , the concentrations of these two radionuclides were ratioed. The ad hoc criterion was established that if the ratio exceeded 1.5 for any soil sample on a property, the property would be classified as being contaminated with tailings. This criterion is independent of the ^{226}Ra and ^{238}U criteria discussed above.

The rationale for this criterion comes from the collection of 327 and 355 background soil samples across the U.S. and analyses for concentrations of ^{226}Ra and ^{238}U , respectively.⁵ In those samples, the mean concentration of ^{226}Ra was found to be 1.1 pCi/g. The mean concentration for ^{238}U was 1.0 pCi/g. These data suggest, as might be expected, that the radium was in equilibrium with the natural uranium in background sites. Without formally accounting for the variation expected in both the numerator and denominator of the ratio, the value of 1.5 seems to be a prudent indicator of the breakpoint between a background ratio and one indicative of tailings. Since there is no standard or guideline to describe "tailings", except for the ^{226}Ra and ^{238}U criteria described above, the classification of properties as tailings-contaminated should be considered qualitative only.

ORE IDENTIFICATION

Ore is more easily identified than tailings in many instances. This is because ore may take the form of rocks which are both visible and characteristically emit more localized gamma radiation. In some cases in Monticello, however, there seemed to be properties on which ore was found, but for which no "rock" existed. Local residents stated that during mill operations, ore dust from ore stockpiles, haul trucks, and the ore crusher were common in portions of Monticello nearest the mill. However, this material appeared to be more "tailings-like" in quality. In such cases, the decision to list a property as contaminated with ore was again made using the ^{226}Ra to ^{238}U ratio. Inverse to the situation with tailings, a property was classified as having ore involvement when the Ra/U ratio was below 1.5. As with the tailings classification, the ore designation should be considered only qualitative because of the probabilistic nature of the Ra/U ratio, and because the classification may include visual sightings alone.

RESULTS

BACKGROUND RADIATION LEVELS

The results of the thirty soil samples taken throughout the city of Monticello are shown in Table 1. The concentration of ^{226}Ra in the 30 samples ranged from 0.88 to 9.7 pCi/g, with a mean concentration of 2.4 pCi/g. The ^{238}U concentrations of the same samples ranged from 0.80 to 7.5 pCi/g and averaged 2.0 pCi/g. The ratio of ^{226}Ra to ^{238}U ranged in these samples from 0.39 to 1.7 and averaged 1.2. A ^{226}Ra to ^{238}U ratio of about unity is generally accepted as indicative of background.

The gamma exposure rate measured at the same 30 locations was much less variable than the ^{226}Ra and ^{238}U concentrations in soil samples. Measurements with a PIC tend to average over a much greater area than the discrete soil samples, and therefore, tend to display much less variability. The range of measurements was from 11 to 15 uR/h with an average value of 13 uR/h.

WALK-ON SURVEYS

The previous listing of properties by Bendix (Table 2) was utilized as a source of potentially contaminated sites which required walk-on gamma surveys. In addition, properties were surveyed which fell into one or more of three categories:

1. possible contamination as indicated by a hit from the mobile gamma scanning van;
2. request for a walk-on survey from the property owner or occupant;
3. evidence of contamination during a walk-on survey of the adjacent property.

A list of 38 such "new" properties which were surveyed during the April 1983, trip is included as Table 3. Property #150 was an owner request, and #151 fell into category 3 above; the remaining 36 properties were all detected by the ORNL mobile gamma scanning van which scanned the entire community.

SOIL SAMPLE RESULTS

Results of soil samples taken on the surveyed properties are listed in Table 4. Nearly 200 samples were collected from the 145 properties that were surveyed. The concentration of ^{226}Ra in the sampled medium (soil or building materials) ranged from background levels to as high as 23,000 pCi/g; concentrations for ^{238}U exceeded that range to a maximum of 24,000 pCi/g. Vanadium and copper concentrations ranged from background to 16,500 and 59,000 ppm, respectively.

The soil sample data in Table 4, coupled with the gamma maps developed during walk-on scanning of the properties, were used to place each property into a contamination category based on the criteria discussed above. These categories, along with the criteria exceeded for each property, are listed in Table 5. Contamination categories are defined as follows:

1. Uncontaminated -- no evidence of contamination; gamma exposure rate, ^{226}Ra and ^{238}U concentrations in soil are within the normal range of background.
2. Building materials -- indication of artificially high gamma exposures emanating from building materials; likely contamination with mill tailings.
3. Ore -- visible ore, high gamma levels associated with rocks, or soil samples with ^{226}Ra to ^{238}U ratio less than 1.5.
4. Tailings -- soil samples with ^{226}Ra to ^{238}U ratio greater than 1.5.

As indicated by Table 5, there are several cases in which a property may fall within one or more contamination categories, but not exceed any of the criteria for inclusion for remedial action. Conversely, properties listed as uncontaminated give no evidence whatsoever of contaminated materials onsite and, therefore, exceed no criteria. For each property that exceeds the ^{226}Ra criterion, exclusive of the 100 m^2 criterion, a figure displaying the contaminated region is included in Appendix II.

SUMMARY OF CONTAMINATED PROPERTIES

The radioactively contaminated status of the properties surveyed in the Monticello community is summarized by Table 6. This table is merely a tally of the various contamination categories and criteria exceeded as listed in Table 5. The summation indicates that 86 properties had ^{226}Ra in excess of 5 pCi/g above background (e.g. greater than 7.4 pCi/g). Forty-four properties appeared to have soil contamination that exceeded 100 m^2 in area. Nineteen properties appeared to have tailings involvement as indicated by the $^{226}\text{Ra}/^{238}\text{U}$, but did not necessarily exceed the 5 pCi/g criteria. Radioactivity in building materials exceeding normal expectations was detected at 21 properties; this was presumably the result of tailings use in mortar or concrete. Ore (either visible, or indicated by the Ra/U) was found on 104 properties. A total of 23 properties were thought to be uncontaminated (radiation levels not above background).

RADIOLOGICAL AND ELEMENTAL COMPARISONS OF MILLSITES

An ancillary activity to the property surveys in Monticello was to investigate the possibility that one or more "signatures" or set of chemical or radiological characteristics could be ascertained for each of the millsites. To this end samples of materials from each pile were analyzed for both radiological and elemental concentrations as previously discussed. This section briefly describes comparisons between those sets of samples.

As shown in Table 7, a total of 17 samples were taken from five piles at the two mill sites. The five piles were chosen because they were distinct and because there was at least anecdotal evidence that the four Monticello piles were created during different types of ore processing.

Mean concentrations for the five types of piles are also shown in Table 7. Data are shown only for ^{226}Ra , ^{238}U , V, and Cu. Although 28 elemental concentrations were determined for each soil sample, only copper and vanadium are reported herein. These appear to be the only two elements which may be used to assign a "signature." A statistical

analysis of the data in Table 7 indicates that mean ^{226}Ra and ^{238}U concentrations for the Dry Valley piles are different from the other piles. The Monticello Vanadium piles (upper and lower) appear to have both higher ^{238}U and V concentrations than the other three piles; however, the variability in the data prevent any statistical significance. The vanadium concentrations are so widely spread that no significant difference ($p > .05$) is observed between any of the piles or processes. The copper concentrations are significantly lower in the Dry Valley piles. However, when the Dry Valley tailings are mixed with undisturbed soil, the concentration of copper would be indistinguishable from natural background concentrations.

Several sets of calculations have been made that attempt to segregate tailings involvement on vicinity properties in Monticello into two groups: those contaminated by Dry Valley tailings and those contaminated by Monticello tailings. The purpose of this section is to describe the results of those calculations and to interpret the results.

The ratioed concentrations of Ra to V and Cu to V for samples taken at the Dry Valley pile and the four distinct Monticello piles have been averaged. The results of these calculations are provided in Table 8. Confidence levels were not calculated for these values because the confidence intervals between concentration ratios between Dry Valley and Monticello soil data overlap. Because this overlap occurs even at the 68% confidence level, there is no way to decide which properties were contaminated by materials from which mills. However, there do appear to be some distinct differences between the mean values for Dry Valley and the mean for the four Monticellos. It should be noted that the variance is large enough and the sample sizes small enough that 95% confidence intervals on the mean Cu/V ratio would overlap zero for several Monticello piles. Therefore, any projections made using these data should be considered very unreliable.

Because the Cu/V ratio had greater separation between the Monticello and Dry Valley samples, the Cu/V ratio was used for purposes of segregation. The breakpoint chosen for this separation was a Cu/V ratio of 0.01. Therefore, any sample with a Cu/V ratio of 0.01 or smaller was considered to have come from Dry Valley. A listing of such samples is given in Table 9. By extension, any samples not listed in Table 9 would

be judged to have come from the Monticello millsite. These differentiations are subject to dispute and are given for information only. This is especially true with the present analysis, because it makes no attempt to consider statistical attributes of the data sets involved in the analysis.

SIGNIFICANCE OF FINDINGS

The results of these surveys have been used to develop a list of properties which may be in excess of EPA criteria for inclusion in the Uranium Mill Tailings Remedial Action Project (UMTRAP), the major DOE project which is active in performing remedial action at properties similarly contaminated to those at Monticello.

Forty-eight properties are believed to be contaminated to the degree that they could be eligible for remedial action under the EPA UMTRA criteria. These properties are listed in Table 10. Additionally, the millsite where the contaminated material most probably originated (based on the preceding section's analysis) is listed in this table. The fact that a property exceeds both the ^{226}Ra and the 100 m^2 criteria does not by extension indicate that a 100 m^2 area is uniformly contaminated to greater than 5 pCi/g. The present mill tailings remedial action criteria (40 CFR 192) were not in effect during the Monticello survey (April 1983). Further, DOE guidance given to the survey team did not dictate compliance to the then-existent draft criteria. Rather, the surveys performed in Monticello by ORNL were for the purpose of determining whether or not tailings contamination existed on the property. Therefore, it is possible that some properties listed as exceeding both the ^{226}Ra and 100 m^2 criteria are not actually in excess of the present EPA standards.

Twenty-one properties were not sufficiently contaminated to warrant an inclusion recommendation, and require further information before a decision could be made. It was recommended that the properties listed in Table 11 receive indoor gamma scanning and/or radon daughter measurements. In June 1984, these 21 properties were the subject of further investigation by the EPA.⁶ Ten buildings were found to have radon daughter concentrations in excess of 0.01 WL or 3 pCi/L of ^{222}Rn . If

was recommended that these ten properties be the subject of additional investigation, and the remaining properties be dropped from further consideration. These properties are given in Table 12. The EPA report describing these surveys is provided in Appendix III.

^aContamination categorized as follows:

Uncontaminated - gamma exposure rate, ²²⁶Ra concentration in soil and ²³⁸U concentration in soil within normal range of background.

Building materials - indication of artificially high gamma exposures emanating from building materials; likely contamination with mill tailings.

Ore - high gamma levels associated with rocks, visible ore, or soil samples with ²²⁶Ra to ²³⁸U ratio <1.5.

Tailings - soil samples with ²²⁶Ra to ²³⁸U ratio greater than 1.5.

^bCriteria:

²²⁶Ra - greater than 5 pCi/g above background in any soil sample taken from property.

²³⁸U - greater than 75 pCi/g above background in any soil sample taken from property.

100 m² - gamma levels or soil samples indicate that either ²²⁶Ra criteria or ²³⁸U criteria exceeded over an area of 100 m² or more.

150	416 S Main	Ore, tailings	M

^aThe property is believed to have concentrations of ^{226}Ra in soil greater than 5 pCi/g above background in the upper 15 cm layer (or >15 pCi/g in any 15 cm layer below the top 15 cm), and gamma radiation levels or soil samples indicate that the ^{226}Ra criteria is exceeded over an area of 100 m² or more.

^bContamination categories are as follows:

Building materials - indication of artificially high gamma exposures emanating from building materials; likely contamination with mill tailings. Properties with building material involvement were automatically included for further consideration.

Ore - high gamma levels associated with rocks, visible ore, or soil samples with ^{226}Ra to ^{238}U ratio <1.5.

Tailings - soil samples with ^{226}Ra to ^{238}U ratio greater than 1.5.

^cMill categories

M - Sample taken on property had Cu/V ratio in excess of assumed lower limit of 0.01, indicating that material was removed from Monticello millsite.

DV - sample taken on property had Cu/V ratio below assumed M lower limit of 0.01, indicating that material had been taken from Dry Valley millsite.

PRELIMINARY

INTRODUCTION

Purpose and Scope

Gamma screening surveys of Monticello vicinity properties were conducted during the summer of 1982 by Bendix Field Engineering Corporation (BFEC). The purpose of the surveys was to provide further data that would be considered in any decision to designate individual properties under the U.S. Department of Energy (DOE) Formerly Utilized Sites Remedial Action Program (FUSRAP). Properties selected for screening were those identified as "anomalous" by previous EPA-sponsored mobile gamma scanning surveys performed in 1971 and 1980 (U.S. EPA, 1972; BFEC, 1982), and the procedures were designed to substantiate the results of those mobile surveys. Gamma screening surveys were also performed on additional properties at the request of the property owners.

The first phase of the work consisted of a review of existing information, a search of property records, and contact with individual property owners. The second phase involved gamma-ray (exposure-rate) surveying of individual properties with scintillometers and pressurized ionization chambers (PICs), and collection and subsequent laboratory analysis for uranium and equivalent uranium of some soil, rock, and building material samples. The third phase consisted of recording the information on sketch maps of each property and on Gamma Survey Report forms, followed by inclusion of this material in a final report.

A total of 114 properties were investigated during the survey (for gamma screening survey locations, see Plate 1 in pocket, back inside cover). Of this total, 98 were identified by the earlier mobile surveys (referred to herein as the 1971 and 1980 surveys) and 16 were investigated at the request of individual property owners. Of the 98 EPA-identified properties, ten were not surveyed because three were previously investigated in detail by a DOE contractor (Arix, 1980 and 1981), two could not be located, and five property owners refused permission to survey. Gamma screening surveys were therefore performed on a total of 104 properties; of these, 35 were also sampled as part of an ancillary study to investigate the problem of determining the outside source of contamination (e.g., uranium ore or mill tailings, or vanadium tailings).

Historical Background

The mill adjacent to Monticello (see Plate 1) initiated processing in mid-1942 with vanadium as its only product. From 1943 to 1946, uranium and vanadium were produced by the mill for the Manhattan Engineer District, and from 1948 to 1956, uranium and vanadium were produced for the U.S. Atomic Energy Commission (AEC). From 1956 to 1960, the mill processed uranium only, for the AEC. Operation of the mill was discontinued in 1960, and the mill tailings ponds were initially stabilized in 1961 to prevent erosion of the radioactive tailings. Further decontamination and stabilization took place in the mid-1970s, leaving the millsite in its current configuration.

Prior to the mid-1970s, radioactive tailings were spread around the city of Monticello, both by man and by natural means. Tailings appear to have been

used as fill material, and as aggregate for mortar and concrete, and to have been carried from the millsite by wind and water erosion. Also, there are recent indications from Monticello residents that some of the low-level radioactive materials in the city of Monticello have come from sources other than the Monticello millsite, e.g., other tailings and ore from nearby uranium and vanadium mines. The 1971 and 1980 surveys mentioned above were conducted to determine the distribution of these low-level materials in the city of Monticello.

The 1971 Survey investigated 494 structures and recorded 62 anomalies. The 1980 Survey investigated 810 structures and recorded 55 anomalies. Combined, this represents 117 anomalies, 19 of which coincide, giving a net total of 98 properties identified as anomalous. Available information is insufficient to explain why there is so little concurrence on anomalous properties between the two surveys. We can only speculate that differences in measurement systems and survey techniques as well as physical changes in properties during the 9 years between surveys are contributing factors. We were also unable to uncover the exact overlap between the 494 and 810 structures surveyed.

In June 1982, the DOE Formerly Utilized Sites Remedial Action Program (FUSRAP) was given responsibility for all remedial actions associated with the Monticello vicinity properties. At this time, FUSRAP does not have an approved set of criteria to be used when considering designation of a vicinity property under FUSRAP; therefore, for the purposes of this report, we have assumed that the EPA standards developed for the DOE Uranium Mill Tailings Remedial Action Program (U.S. EPA, 1983) are applicable to FUSRAP.

FIELD OPERATIONS

Preliminary Activity

Following review of the 1971 and 1980 surveys, a property record search was conducted on all properties identified as anomalous. This search identified ownership and, in some instances, the names of lessees or occupants. However, building construction dates could not be established in the San Juan County Records office, and only a few construction dates were located in the County Assessors office. The city of Monticello issues building permits, but the files are destroyed at the end of each calendar year to make room for the coming year's permit activities.

Thus, to develop adequate property ownership records, a combination Permit Form/Questionnaire together with a cover letter and an addressed, stamped, return envelope were sent to each property owner (Appendix A). As the permit forms were returned, the project field leader contacted property owners and/or tenants to arrange appointments for the surveys to be conducted.

Prior to initiating the actual surveys, an informational meeting was held in the San Juan County Courthouse with the San Juan County Commissioners, the Mayor of Monticello, representatives of the Utah State Health Department, and project leaders from DOE and Bendix. A press release explaining the purpose and nature of the project was issued to the local press shortly after the meeting (Appendix A).

Gamma Screening

Prior to conducting the actual gamma survey at an individual property, a preliminary sketch map of that property was prepared. Each map showed the locations of fences, shrubs, gardens, driveways, sidewalks, and structures, as well as floor plans and the grid network that was to be used while performing both the indoor and outdoor surveys.

Two instruments were used for the surveying: pressurized ionization chambers (PICs) and hand-held scintillometers. The PICs were used to take measurements (3-ft elevation) at some grid-line intersections; these measurements were to be used later to correct the scintillometer readings to true exposure-rate values (see below). The scintillometers were used to take measurements (3-ft elevation and on the surface) at all grid-line intersections. All instruments were field-checked daily with radium check-sources to ensure that calibrations were stable, and weekly calibrations using a point-source geometry were performed at the laboratory.

The gamma readings were recorded on the preliminary sketch maps in the field. The sketch maps were later drafted, and information from them and from field notes was transferred to the Gamma Survey Report forms along with a photo of each property. The completed report form and sketch map for each surveyed property are contained in Appendix B. The following conventions were used to present the PIC data and the uncorrected scintillometer data on the maps:

\boxed{A} = 3-foot PIC reading (in true $\mu\text{R/hr}$ values)

$\frac{15}{12} = \frac{\text{3-foot scintillometer reading}}{\text{surface scintillometer reading}}$ (in uncorrected $\mu\text{R/hr}$ values)

The average background exposure rate for the Monticello area is taken to be 15 $\mu\text{R/hr}$, based on work done under the authority of the Surplus Facilities Management Program (Abramiuk, 1983).

The correction equation to convert scintillometer readings to true exposure rate was derived by least-square fitting a straight line to 244 points representing both indoor and outdoor PIC/scintillometer data pairs for the Monticello area (Figure 1). The result is

$$\text{scintillometer/CORR} = 0.44 \text{ scintillometer/UNCORR} + 8.1 \mu\text{R/hr}$$

where

$$\text{scintillometer/CORR} = \text{true exposure rate in } \mu\text{R/hr}$$

$$\text{scintillometer/UNCORR} = \text{scintillometer readings in } \mu\text{R/hr}$$

Note that the highest uncorrected scintillometer value used in this derivation was 80 $\mu\text{R/hr}$, so the correction equation becomes increasingly unreliable at higher and higher values.

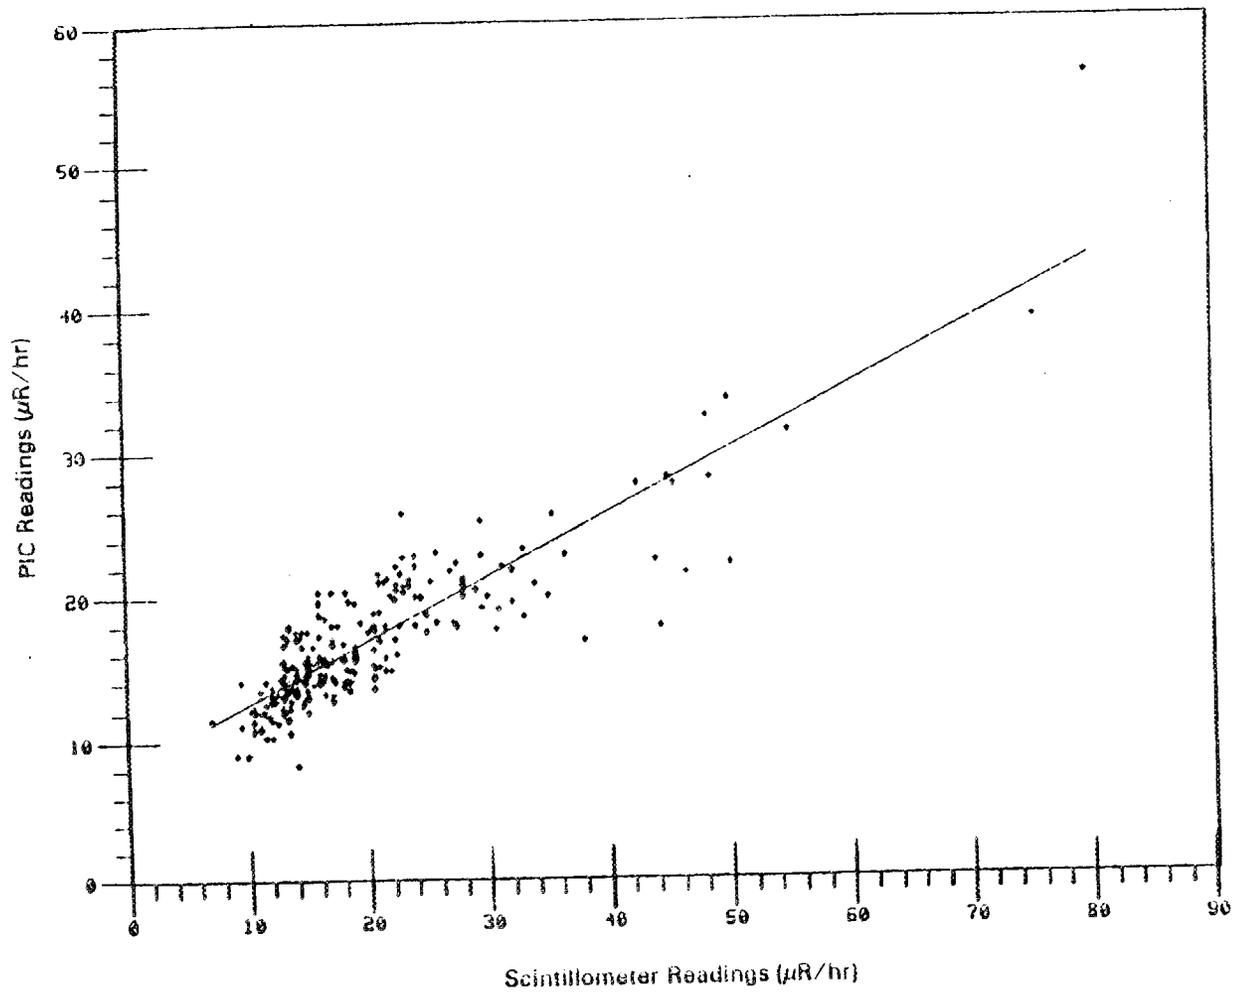

Figure 1. PIC Readings Versus Scintillometer Readings

Sampling

Supplemental to the original scope (gamma screening only) of the project, an arbitrary number of surface samples were taken from some of the properties to explore the problem of determining the outside source of contamination. These samples represented a variety of materials and a wide range of radioactivity, and were used to investigate the possibility of using a radiometric signature to distinguish residual uranium mill tailings from uranium ore or vanadium mill tailings contamination originating at other sites. To this end, laboratory analyses were performed on 60 samples taken from 35 properties (see locations on individual property sketch maps in Appendix B) to determine "chemical" uranium (U) and "equivalent" uranium (eU). The former was determined by the fluorimetric or colorimetric method, as appropriate; the latter was determined by gamma spectroscopy using either a sodium iodide or germanium detector and either the 1765-keV or the 609-keV Bi-214 peak, as appropriate.

Using results from the analyses, the ratio eU/U was calculated for each sample based upon the assumption that if the ratio is less than or approximately equal to 1 then this sample probably contains uranium ore or vanadium tailings in varying degrees of disequilibrium, and if the ratio is significantly greater than 1, residual uranium mill tailings may be present.

SURVEY RESULTS

Gamma Screening

A total of 114 properties were investigated, and gamma screening surveys were performed on 104. The previous EPA-sponsored mobile surveys identified 98 properties as anomalous of which two were not located, five property owners refused permission to conduct surveys, and three were the subject of previous radiologic and engineering assessments. In addition to the remaining 88 properties, 16 properties were surveyed upon request by the owners.

The complete screening survey results for all properties investigated are presented in Appendix B. In addition, Figures 2A through 2F are bar graphs which illustrate and compare the corrected high inside gamma (HIG), high outside gamma (HOG), and low outside gamma (LOG) readings for each property.

Table 1 lists each property by its screening survey number and gives a summary of pertinent and specific information for each property, including the address and the corrected values for the HOG, HIG, and LOG readings.

Table 2 provides an overall summary of survey results by listing properties by number and land-use designation, according to whether or not true (corrected) exposure rates exceeded certain values tied directly or indirectly to EPA standards. The table also indicates the degree of need for further study in order to designate these properties as part of FUSRAP, based upon the assumptions of EPA standards and the presence of residual uranium mill tailings from the Monticello millsite.

In Table 2, properties with HIG values of 35 $\mu\text{R/hr}$ or greater are isolated because they exceed the EPA exposure-rate standard of background [15 $\mu\text{R/hr}$ for the Monticello area (Abramiuk, 1983)] plus 20 $\mu\text{R/hr}$. Properties with HOG values of 20 $\mu\text{R/hr}$ or greater are isolated based on a similar criterion (background plus 3-5 $\mu\text{R/hr}$) found to be successful in identifying contaminated lands under the Grand Junction Remedial Action Program (H. Langner, BFEC, personal communication, April 1983). However, the HOG exposure-rate criterion should not be used to supplant the EPA radium-in-soil standard.

Sampling

A compilation of results from spectral (eU) and chemical (U) analysis of the 60 samples taken from 35 of the properties is presented in Table 3. Also included is the radium concentration for each sample based on the conversion equation by George and Knight (1982):

$$\frac{\text{pCi}}{\text{g}} \text{ Ra-226} = 0.3337 \text{ (wt-ppm eU)}$$

The eU/U ratios vary from 0.22 to 5.56, and, on the basis of the expected behavior of the ratio for uranium mill tailings versus uranium ore and vanadium mill tailings, it is clear that two properties (100 and 104) contain uranium tailings. (We can make the assumption that they are from the Monticello millsite.) Note that in Table 2 property 104 has been shown to exceed the EPA exposure-rate standard and property 100 is a "possible." If we assume a cutoff value of the ratio to be 1.5 (not a statistically based number) for the probable presence of uranium mill tailings, then properties 39, 85, 86, 88, 95, and 102 fit that category (Table 3); from Table 2, property 39 has been shown to exceed the EPA exposure-rate standard and the five remaining properties are in the "possible" category. Several other properties with higher uranium concentrations (e.g., 4, 43, 48, and 105) clearly contain uranium ore and/or vanadium mill tailings.

The data in Table 3 indicate the distinct possibility of using the eU/U approach to help determine the origin of contamination on individual Monticello vicinity properties. However, the final discrimination procedure would, of course, have to result from a more thorough, systematic, and statistical study than that presented above.

DISCUSSION AND CONCLUSIONS

Until a definitive study (see below) can be done to obtain a reliable method to determine the outside origin of radioactive materials on individual properties at Monticello, we cannot make a firm recommendation that any of the properties investigated here be designated (assuming EPA standards) under FUSRAP. However, from Table 2, we can say that 15 properties are very good candidates (especially 39 and 104, based on sampling results); 50 more properties are "possibles" and should be surveyed with in-situ radium measuring instruments to facilitate direct comparison with the EPA radium-in-soil standard. Of these 50 properties, at least 5 (85, 86, 88, 95, and 102) should be investigated first because of the probable presence of uranium mill

tailings. Finally, 39 properties, as shown in Table 2, are poor candidates for designation, and further measurements should be given the lowest priority.

It is interesting albeit disconcerting that 9 of the 16 "requested" properties (none shown as anomalous in the 1971 and 1980 mobile surveys) have HOG readings ≥ 20 $\mu\text{R/hr}$, and are therefore "possibles." On the other hand, 39 of the mobile survey anomalies could not be substantiated. These facts bring into question the practice of relying mainly on mobile scanning surveys to identify individual properties for further on-site investigation.

The ancillary sampling study was by no means rigidly designed or statistically based. The results are encouraging, though, that a definitive study could lead to determination of criteria for distinguishing uranium mill tailings from uranium ore or vanadium mill tailings. Such a study is proposed in Appendix C.

SAMPLE COVER LETTER, PERMIT FORM/QUESTIONNAIRE,
AND PRESS RELEASE

Department of Energy

P.O. Box 2567
Grand Junction, CO 81502-2567

June 7, 1982

Dear Property Owner:

As you may know, the United States Atomic Energy Commission operated the Monticello uranium mill from 1949 until shutdown in January 1960. Stabilization of the mill tailings piles was completed in 1962. Dismantling of the mill was completed in 1964 and the ore stockpile areas were cleaned up during 1974-1975.

In 1979 the U.S. Department of Energy (DOE) established the Surplus Facilities Management Program to decommission DOE Facilities surplus to the Department's needs, to eliminate potential hazards to public health and to the environment, and if possible to permit other productive uses of the facilities and/or property in the future.

In cooperation with the DOE and as part of this remedial action effort, the U.S. Environmental Protection Agency (EPA) and representatives of the Utah State Health Department have conducted preliminary surveys to determine if mill tailings were used or transported to any vicinity properties in Monticello. Your property has tentatively been identified as having elevated radioactive readings in comparison to the normal background radioactivity level in the Monticello area.

The purpose of this letter is to obtain your permission to conduct a gamma survey of your property to determine whether radioactive materials, and especially uranium mill tailings deposits, are in fact present. The survey will be primarily looking for uranium mill tailings but may also identify objects such as luminous-dial instruments, propane tanks, petrified wood or bone, and ore samples that may have caused your property to be identified for inclusion in the gamma survey effort. Firebrick and some brick and tile may also contribute to elevated readings due to the natural radioactivity of the material used in their manufacture.

The gamma survey will be conducted by Bendix Field Engineering Corporation (BFEC), contractor to the DOE and based in Grand Junction, Colorado. A permission and information form granting the survey team (two persons) access to your property is enclosed for your signature. Following your signing and returning of the form, and its acceptance by DOE, you will be contacted directly by the team's supervisor for schedule arrangements.

June 7, 1982

While a minimum need is currently identified for the collection of soil and/or construction samples for assay, this letter warrants that 3FEC will promptly repair, to the fullest extent practicable, any areas disturbed by digging, sampling or other work performed under the attached agreement.

Your assistance in support of this effort to eliminate any potential radioactive hazard in your community is greatly appreciated. Should you have any questions, please contact one of the following:

Permission and Information Form
Return Envelope

Dear Property Owner:

To make this survey more convenient for you and to assist us in scheduling survey personnel, please complete this Permission and Information form and return it in the enclosed stamped and addressed envelope.

Address and/or legal description of your property in Monticello _____

Your telephone no. _____

Please indicate use of property (example: home, business, vacant lot, rental property, etc.) _____

_____. Approximate date of original construction _____

Approximate date(s) of subsequent construction _____

If rental, lessee's name _____

Lessee's telephone no. _____

The survey usually takes about 2 hours to complete. Please indicate the most convenient days and times for us to do the survey (example: Mondays, Wednesdays and Fridays from 2:15 pm to 6:00 pm). Preferred days _____

Preferred times _____

Your comments _____

I hereby grant DOE and its designees the right to enter on my property for the purpose of conducting radiological surveys.

Your address _____

Owner's Signature _____ Date _____

Lessee's Signature _____ Date _____

PRESS RELEASE ISSUED TO LOCAL PRESS FOLLOWING INFORMATIONAL MEETING

A radiological survey of the former uranium millsite and of a number of private properties in Monticello, Utah, will be conducted during June by personnel of the Bendix Field Engineering Corporation, it was jointly announced today by the Utah Department of Health and the U.S. Department of Energy (DOE).

Bendix, operating contractor for DOE's Grand Junction (Colorado) Area Office, will also award a contract to drill numerous shallow holes in the vicinity of the former millsite. These assessment holes will allow scientists to study the natural background radiation of the Monticello area, the level of radiation at the millsite, and the effects on groundwater from the uranium tailings at the site.

Previous surveys conducted by state and federal agencies have identified about 90 properties in the Monticello area which may have levels of radioactivity which exceed normal background levels. Bendix personnel will be contacting property owners in an attempt to further define the limits and extent of possible mill tailings located on these properties. The elevated radiation levels may be caused by mill tailings, ore samples, or masonry construction materials which typically emit a higher level of natural radioactivity. Some other materials which naturally emit higher levels of radioactivity on occasion include petrified wood or bones, fire brick, tile, and propane.

The purpose of the Monticello survey is to verify the presence or absence of uranium mill tailings, and to determine the source of radiation on each property. The Department of Energy will utilize the information to prepare a basic cost estimate which will be submitted to Congress on which to base a decision to fund possible future remedial action activities in the Monticello area; and to determine the need for future surveys based on Environmental Protection Agency (EPA) standards. EPA is scheduled to publish guidelines in January 1983 establishing safe working levels and radiation exposure limits to reduce potential hazard to the public and to the environment.

GAMMA SURVEY REPORTS AND MAPS
FOR MONTICELLO PROPERTIES

EXPLANATION OF NUMBERS USED ON GAMMA SURVEY REPORTS

The following categories are listed on the Gamma Survey Report form with the appropriate numbers for each property. Refer to this listing for an explanation of those numbers.

Property Classification

0. Vacant Lot
1. Single-Family Residence
2. Multi (<4) Family Residence
3. Multi (>4) Family Residence
4. Motel, Hotel, or Hospital
5. Single Business (in one unit)
6. Multiple Business Unit (connected)
7. School
8. Church
9. Other

Gamma Map

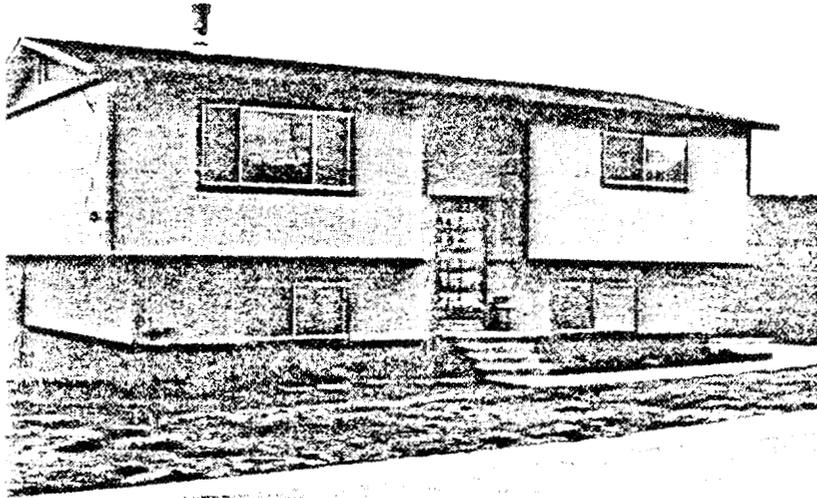

0. None
1. Completed
2. Occupant Refusal
3. No - Ask Owner
4. Owner Refusal
5. Owner Refusal; Signed Refusal Form
6. No One To Contact
7. No - Bad Address
8. Outside Only
9. Special Scheduling
10. Other

Tailings Use

0. None
1. Under
2. Away
3. Under-Away
4. Possible
5. Unknown

Under: Gamma readings are 20 μ R/hr or greater inside and/or within 10 feet of habitable structure.

Away: Gamma readings are 20 μ R/hr or greater further than 10 feet from habitable structure.

APPENDIX III

**EPA SURVEY OF 21 PROPERTIES WITH POTENTIAL
MILL TAILINGS CONTAMINATION IN MONTICELLO**

EPA SURVEY OF POSSIBLE MILL TAILINGS CONTAMINATION IN
MONTICELLO, UTAH
JUNE, 1984.

INTRODUCTION

In June, 1984, a radiation survey of 21 buildings in Monticello, Utah, was completed by the EPA Region VIII Radiation Programs Branch, assisted by personnel from the Office of Radiation Programs - Las Vegas Facility (ORP-LVF), the Region VIII Field Investigation Team, and the Utah Department of Health. The survey locations were suggested by the U.S. Department of Energy (DOE), which had previously conducted extensive gamma radiation surveys in the town. Prior arrangements to survey the properties were made by the Southeastern Utah Health District. Interior radon and radon daughter measurements were made in 19 of the 21 buildings, and interior gamma radiation measurements were made in 10 of them not previously surveyed by DOE. Based on the short-term (grab) sample results, none of the buildings surveyed by EPA exhibited radon daughter concentrations (RDC's) in excess of 0.04 working levels (WL), 10 buildings had measurements on one or more levels exceeding 0.01 WL or 3 picocuries of radon (Rn-222) per liter of air (pCi/l). None of the buildings had overall average exposure rates in excess of 20 microrentgens per hour (uR/h, corrected) above the prevailing local background, and only one building had an individual room with greater than 20 uR/h above background. A summary of the results is shown in Table 1.

BACKGROUND

Monticello has a population of 1200 and is located about 290 miles southeast of Salt Lake City. It is the seat of San Juan County and, in area, the largest county in Utah. It is also rich in mineral deposits, being geologically an extension of the Colorado Plateau. Mining for radium, vanadium, and uranium has been carried out here since the late 19th century. In the early 1940's, the Federal Government built a vanadium mill in Monticello in order to assure a domestic source of this strategic metal. In 1947, the mill was acquired by the Atomic Energy Commission (AEC) and subsequently converted to uranium production -- a relatively simple matter since both materials are found in the same ore. For this reason the mill tailings from both processes were essentially identical, and both contained radium and other radioactive materials as waste products. After the mill itself was closed and dismantled in 1960, the tailings were stabilized on the site in four large piles. In addition to the AEC operation, other mills of various sizes and degrees of success have produced either uranium or vanadium at several locations throughout San Juan County, some still in operation to the present day. One of them produced vanadium in the 1931-39 era, and is located about 25 road miles north of Monticello in Dry Valley. Although this mill was closed over forty years ago, a small quantity of tailings remained on the site in an uncontrolled fashion until 1984, when the owner took steps to consolidate and cover them at the request of the State.

Despite some efforts at control, uranium and vanadium mill tailings were used for construction and fill material at various locations in Monticello. Furthermore, areas near the AEC mill were subjected to windblown tailings from

the piles before they were stabilized and covered. Several investigations by EPA, DOE (successor agency to the AEC), and the State of Utah have identified fairly well those properties with elevated levels of gamma radiation which may have resulted from the presence of tailings. The DOE surveys of 1982-83 identified 147 locations of elevated gamma radiation levels. Subsequent work identified 44 of those properties with gamma radiation levels or radon concentrations in excess of EPA Standards for Remedial Actions at Inactive Uranium Processing Sites (40 CFR 192), two of which have since been cleaned up through an EPA Planned Removal Action. Of the remaining 103 properties, 39 showed evidence only of ore (as opposed to tailings), 24 were judged to be uncontaminated, 15 have not been classified, and 4 sites were not surveyed because of the owners' unavailability or denial of access. The remaining 21 properties were surveyed for interior gamma radiation exposure rates and/or radon/radon daughter concentrations as described below.

Because of the previous ownership of the mill by the AEC, DOE has retained responsibility for the Monticello millsite and the tailings that remain there. DOE also has the authority and responsibility to clean up vicinity properties away from the millsite which have been contaminated by waste products identified as originating from the AEC operation, and it has adopted the EPA standards from 40 CFR 192, with minor modifications, as the cleanup criteria which will be applied to the contaminated Monticello properties. For properties contaminated with material originating from other than the Monticello millsite, however, DOE has stated they have neither the authority nor the responsibility for remedial action. In these cases, cleanup of the contamination may be carried out under the provisions of the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, or Superfund) if certain requirements are met, and the responsibility for the cleanup would be shared by EPA and the State. At the 21 sites where DOE did not have adequate data to determine their eligibility for remedial action, EPA Region VIII and the State of Utah cooperated in surveying these buildings, some of which were suspected of having been contaminated by tailings from the old Dry Valley mill.

SURVEY METHODS

As noted previously, DOE suggested 21 properties for this survey because information from previous surveys was inadequate to determine whether these properties exceeded the standards in 40 CFR 192. It was proposed that grab samples for radon and radon daughters be taken in all of these buildings according to the inclusion procedures given in the Vicinity Properties Management and Implementation Manual (VPMIM, UMTRA-DOE/AL-050601, June, 1984), which basically gives the following standardized conditions for the sampling:

- recent outside measurements of Rn-222 have not exceeded 2 pCi/l
- wind speeds in the area have not exceeded 10 mph for the preceding 4 hours
- doors, windows, and openings in the structure have been closed for the preceding 12 hours
- ventilation systems which introduce outside air into the structure have not operated during the preceding 12 hours

In certain cases, all of these conditions could not be met, and those exceptions are noted in Table 1 as well as on the individual data sheets in

Appendix A. The sampling equipment was provided jointly by EPA Region VIII and the ORP Las Vegas Facility (LVF) and was operated according to LVF Standard Operating Procedure #13, included here as Appendix B. At LVF, radon measurements are calibrated by emanation of National Bureau of Standards (NBS) Reference Solutions of Ra-226, and are checked by periodic intercomparisons coordinated by the Environmental Measurements Laboratory of the Department of Energy. Radon daughter measurements are calibrated through alpha scintillation counting systems standardized with electroplated disk alpha sources which have been compared to similar sources provided by the NBS. Air volume measurements are compared to a wet test meter which is in turn checked periodically with a laminar flow apparatus whose calibration is traceable to NBS. Radon daughter calibrations have been periodically verified by intercomparisons among several recognized national laboratories.

At 10 of the 21 buildings, only gamma radiation surveys of the exterior and grounds of the property had been conducted previously by DOE, so indoor gamma measurements were made by the EPA survey teams throughout these buildings. Measurements were obtained with Ludlum model 19 scintillometers calibrated by the LVF, and the exposure rates indicated by the scintillometers were corrected to the exposure rate determined by a Reuter-Stokes model RSS-111 pressurized ionization chamber through a linear regression of comparative measurements at several selected exposure rates. The surveys were conducted in accordance with the inclusion procedures specified in the VPMIM, and the data are summarized in Table 1. Data for each individual site are found in Appendix A.

Site visits were made by three survey teams during the period June 19-21, 1984. For those buildings that were occupied residences, every effort was made to schedule the visit in the early morning hours before normal family activities would increase the household ventilation. Homeowners were requested to keep the buildings tightly closed during the preceding night, but some exceptions were noted. Several of the homes were vacant, which simplified the scheduling process. Commercial buildings were usually visited in the morning as well, so measurements could be made prior to the start of the business day. All scheduling arrangements were made by the District Sanitarian for the Southeast Utah Health District, who resides in Monticello, and his efforts greatly increased the efficient utilization of the survey teams. The weather was fair during the period of the survey, with only light to moderate breezes on the mornings of June 19 and 20, and the barometric pressure was stable.

At the request of the State, integrated radon daughter measurements were made at all of the sites where electrical power was available. Radon Progeny Integrating Sampling Units (RPISU's), provided by LVF, were installed in 17 buildings during the site visits and were left to sample for a minimum of one week. The RPISU operating procedure is included in Appendix B. One sampler operated for only 10 hours and a second for 56 hours, but the remaining samplers operated for well over 100 hours. These RPSIU data generally agreed with the grab sample data and the results for both are shown in Appendix A. While a single integrated measurement is insufficient to include or exclude a property from further consideration, its agreement with the grab sample measurements serves to strengthen one's confidence in the validity of the overall results. This expression of confidence is especially important in the summer months, when it may be difficult to obtain valid measurements due to occupant-induced ventilation of the buildings.

RESULTS

Twenty-one buildings in Monticello were suggested for radon and radon daughter measurements by DOE, as the data previously acquired from gamma radiation surveys were inadequate to either include or exclude the buildings from remedial action based on standards in 40 CFR 192. One owner (#119) refused to allow access by the survey teams to his property, and one building (#37) was judged insufficiently closed to allow radon or radon daughter measurements to be meaningful. Measurements were made in the remaining 19 buildings, although 3 of them may have been inadequately closed for the required time before sampling. These were numbers 2, 16, and 118. Measurements were made on the ground level of each building and on any levels below grade. None of the buildings had habitable levels above the ground floor. Duplicate samples for radon daughters were taken at each location, and the results averaged to estimate the RDC on a given level. Usually only one duplicate sample pair was taken on each level unless the building had only a single habitable level. In those cases, samples were usually taken at two locations. Because of equipment limitations, no duplicate radon samples were taken.

None of the 19 buildings surveyed by EPA showed RDC levels greater than 0.04 WL based on the grab samples taken under closed conditions. This is the level used by DOE for inclusion of a property in the remedial action program, as other studies have shown that this level is highly indicative of an annual average RDC of greater than 0.02 WL, the maximum level permitted by 40 CFR 192. Ten of the 19 buildings surveyed had an RDC greater than 0.01 WL based on the grab samples, the level below which DOE will exclude a particular property from further consideration for remedial action. These 10 buildings are listed in Table 2 with the results of both grab sample and integrated measurements. Eight of the remaining 9 buildings had neither gamma exposure rates nor RDC's exceeding the inclusion criteria. The ninth building, a single family residence, did not exceed the criterion for RDC but did have a single room where the average exposure rate exceeded 20 uR/h above background. These locations are listed in Table 3. Also included in Table 3 is location #37, a commercial property in which no radon daughter measurements were made because it could not be adequately closed, and in which the average exposure rate did not exceed the inclusion criterion. As noted previously, only one of the 21 suggested buildings was not surveyed because the property owner denied permission for access to the survey team. In November 1980, a RPISU sample of 91.5 hours, taken in the living area of that house, indicated 0.05 WL. Followup samples in September and October of 1981 indicated 0.03 WL in a closet and 0.4 WL in the crawl space. The latter samples were for periods of 334.7 hours and 240.3 hours, respectively. There is as yet no direct evidence of the presence of uranium mill tailings, so far as EPA is aware.

CONCLUSIONS

Of the 21 buildings suggested for radon daughter measurements by DOE, 10 buildings had one or more floors with the RDC greater than 0.01 WL, as noted in Table 2. According to the protocol in the YPMIM, these buildings should be investigated further to determine the annual average RDC, and the source of the contamination must be defined. Based on visual observation and discussions with the homeowners, it is possible that 8 of these 10 buildings contain tailings from the Dry Valley millsite in the mortar of the exterior or interior masonry.

The 10 buildings listed in Table 3 do not exceed any criteria for radon daughter concentrations, according to the measurements made by EPA, and only one of them had gamma exposure rate greater than 20 uR/h above background. It is recommended that these buildings be dropped from further consideration for any remedial action, and that the property owners be so notified as soon as possible.

One building suggested by DOE was not surveyed by EPA because the owner denied the survey team permission for access. Integrated measurements made in 1980 and 1981, however, strongly suggest that the annual average RDC could exceed 0.02 WL. If the 1983 exterior gamma radiation survey by the DOE contractor provided any evidence of the presence of mill tailings, then some additional consultation with the homeowner is probably indicated. The homeowner was informed of the results by the District Sanitarian following the '80-'81 tests, so unless further action is contemplated, no further notification would be required.

ACKNOWLEDGEMENTS

The teams conducted these surveys in a very professional manner, and with extremely short lead time. The members of the teams were as follows:

Mr. Philip Nyberg, EPA Region VIII
Dr. Frederick Au, ORP-LVF
Ms. Edith Boyd, ORP-LVF
Ms. Shirley Duran, ORP-LVF
Mr. John Stevenson, Ecology and Environment, Inc. (EPA/8 F.I.T.)

** Scintillatometer readings corrected to pressurized ionization chamber measurements by the following relations:

$$\text{EPA measurements: scint (CORR)} = (0.43 \text{ scint (UNCORR)} + 7.7) \text{ uR/h}$$

$$\text{Bendix F.E.C. measurements: scint (CORR)} = (0.44 \text{ scint (UNCORR)} + 8.1) \text{ uR/h}$$

$$\text{where: scint (CORR)} = \text{actual exposure rate, in uR/h}$$

$$\text{scint (UNCORR)} = \text{scintillometer reading, in uR/h}$$

* Measurements made by Bendix Field Engineering Corp. for DOE/GJAO

Note 1. Front door was open when survey team arrived; moderate breeze

Note 2. Rear (south) door was open when survey team arrived; moderate breeze; measurements made in northwest bedroom, farthest from the open door

Note 3. Living room window open when survey team arrived; moderate breeze

Note 4. Sample taken from front showroom, which was relatively tight; rear area very drafty

APPENDIX B

Standard Operating Procedures

Interpretation of Computer Printout for Indoor Radon Progeny Sampling Results

Location Code and Run Number

The first column on the printout contains a five-digit code which indicates the sample location. It is followed by a two-digit number which shows the "run number" or sample number, at that location. Samples at a given location are numbered in chronological order of collection.

Invalid Sample Results

Individual sample results may be invalid for a number of reasons. Such results are designated on the printout by a notation "NV-X" following the "Working Levels" column. The "NV" notation indicates "not valid," and the digit codes, indicating the reason, are as follows:

- NV-1 No measurable "off" flow rate at the end of sampling period due to pump failure, "plugged" filter, etc.
- NV-2 Insufficient exposure to radon progeny; i.e., less than one working level liter was measured for the sampling period.
- NV-3 Invalid average working level due to insufficient time lapse between sample collection.
- NV-4 Error made during TLD readout.
- NV-5 Damaged filter or sampling head.
- NV-6 Miscellaneous.
- NV-7 RPISU samplers run simultaneously in different areas of the same location.
- NV-8 RPISU only run during "working hours."
- NV-9 Special study.
- NV-0 RPISU clock failure.

Invalid sample results appear on the printout in order to maintain a record of the sample, but invalid results are not included in calculating the average working level.

Sample Averaging

The "Average Working Level" appears on the right-hand side of the page at the last sample for each different location. This is a simple arithmetic average of all the individual working level measurements at that location. It is not a time-weighted average. Note that "NV" results are not included in the Average Working Level.

ORP-LVF SOP #1

OPERATING INSTRUCTIONS FOR THE EPA WORKING LEVEL MONITOR
(With Top-Mounted Timer)Purpose and Principle of Operation

This instrument, formally known as the RPISU (Radon Progeny Integrating Sampling Unit), is designed to measure the alpha particle energy from airborne radon progeny, or daughters. This alpha energy is then converted to working level units, a commonly-used measure of the health hazard from the radon progeny. Unlike most working level samplers, the RPISU measures the average, or integrated, working level over a period of days, rather than taking an instantaneous reading.

A small pump pulls air through the detector head, shown in exploded view in Figure 1. The particulate radon daughters are trapped on the filter paper. As the short-lived daughters decay, their alpha energy is deposited in the thermoluminescent dosimeter, or TLD, adjacent to the filter. A second TLD, shielded from the filter by a metal washer, responds to the more penetrating gamma radiation from external background. The reading on the second (gamma) TLD is subtracted from that on the first one (the alpha TLD) to give a net reading due to alpha energy from the filtered radon daughters.

The TLD material has the property of absorbing radiation energy, then emitting a proportional amount of light when it is heated later under controlled conditions. Therefore, the detector heads must be sent back to the EPA laboratory, where they are taken apart, the TLD's removed, and "read out" in a special instrument to measure the amount of light, and consequently the amount of radiation energy absorbed during the sampling period. Knowing the radiation energy absorbed and the volume of air sampled, the average working level during the sampling period can be calculated.

Operating Procedure

To start a sample:

1. Plug the sampler into a 115-volt AC outlet. The sampler has about three feet of cord, which may have been tucked into one of the ventilation holes at the bottom of the sampler. The sampler should start to run immediately. If it does not, see "Troubleshooting" section.
2. Record the location, starting date, and starting reading from the running time meter, on the data envelope which contains a sampling head. (See Figure 2) Also record the RPISU pump number.
3. Place the sampling head in the end of the air inlet tubing. The connection is a twist-lock fitting. (Inlet tubing may be tucked into one of the ventilation holes at the top of the sampler.)

4. Allow the pump to run for a minute or two, then insert the flow meter fitting into the open end of the sampling head. Record the flow rate (in liters per minute) on the envelope. Also record the identification number or letter of the flow meter (this is written on the inside of the white backing, and is read through the lucite body of the meter) and initial the envelope. Disconnect the flow meter (do not collect sample through the flow meter).

To take a sample off:

1. Take a flow rate measurement as at the start of sampling. (See 6 under "Troubleshooting" section if pump is not running).
2. Record the pertinent data in the "End of Sampling" column on the envelope.
3. Replace the sampling head in the envelope, and mail to the EPA laboratory, using the preaddressed padded envelope furnished.

Handy hints and troubleshooting:

1. It is essential that all the information on the data sheet be filled in.
2. The unit is designed for indoor use only.
3. A weekly sampling period is recommended, although a few days longer is okay if dusty conditions are not encountered. A sampling head should not be left on the sampler for more than two weeks.
4. The pump is protected by both pressure drop and thermal overload switches, both of which are bypassed by a reset button. If the filter becomes clogged from dust, smoke, or other particulates in the air, the unit will shut off when the air flow drops below 1.0 lpm. Therefore, it is suggested that a sampling location with relatively clean air be selected, since the unit is quite sensitive in this respect. For example, rooms with a heavy concentration of cigarette smoke have been known to stall the sampler after a relatively short sampling time.
5. If the sampler goes off for any reason, such as a power outage, from being unplugged, from a pressure or thermal overload, etc., it will restart automatically when power is restored. If it is not running, depress the restart button, accessible through one of the top vent holes, and observe the sampler for at least five minutes to be sure it continues to run. If it shuts off within a few minutes the filter is probably overloaded, as discussed above, and the head must be changed.
6. If a head is removed under the above conditions, be sure to take the "off" flow rate reading. This can be done by holding the reset button down long enough to obtain the reading with the flow rate meter. Both "on" and "off" flow rates are essential to calculate the working level. Do not record the "off" flow as zero, unless the pump is completely broken.

PUMP #:	LOCATION CODE:		NOTES:
	START OF SAMPLE	END OF SAMPLE	
DATE:			
TIME METER HRS. & TENTHS	•	•	
FLOW RATE LITERS/MIN	•	•	
ROTAMETER NO.

FILTER #:	ALPHA TLD #:	GAMMA TLD #:	

3" x 5" manila envelope

Data to be entered at the time the TLD filter holder units are prepared for use:

Filter : number stamped on filter holder

Alpha TLD : number of TLD disc nearest the filter

Gamma TLD : number of TLD disc above steel washer

In addition, the preparation date should be stamped under "NOTES."

Data to be entered by field personnel at time of use:

Pump : number on air pump motor

Location code: number assigned to the sampling location, and
location address

Start of sample: enter all data in the column - date, time meter reading
(to nearest 0.1 hr), flow rate through the filter,
rotameter number used to determine flow rate, and
initials of person installing the sampler.

End of sample: enter all data in column - same as Start Column

Notes: any comments on sampler operation, etc.

Figure 2 Individual TLD sampler field record (envelope).

BY PCN/SAK-RP DATE 6-28-84 SUBJECT Radon/Radon Daughter SHEET NO. 1 OF 1
CHKD BY DATE Sampling Train Layout JOB NO

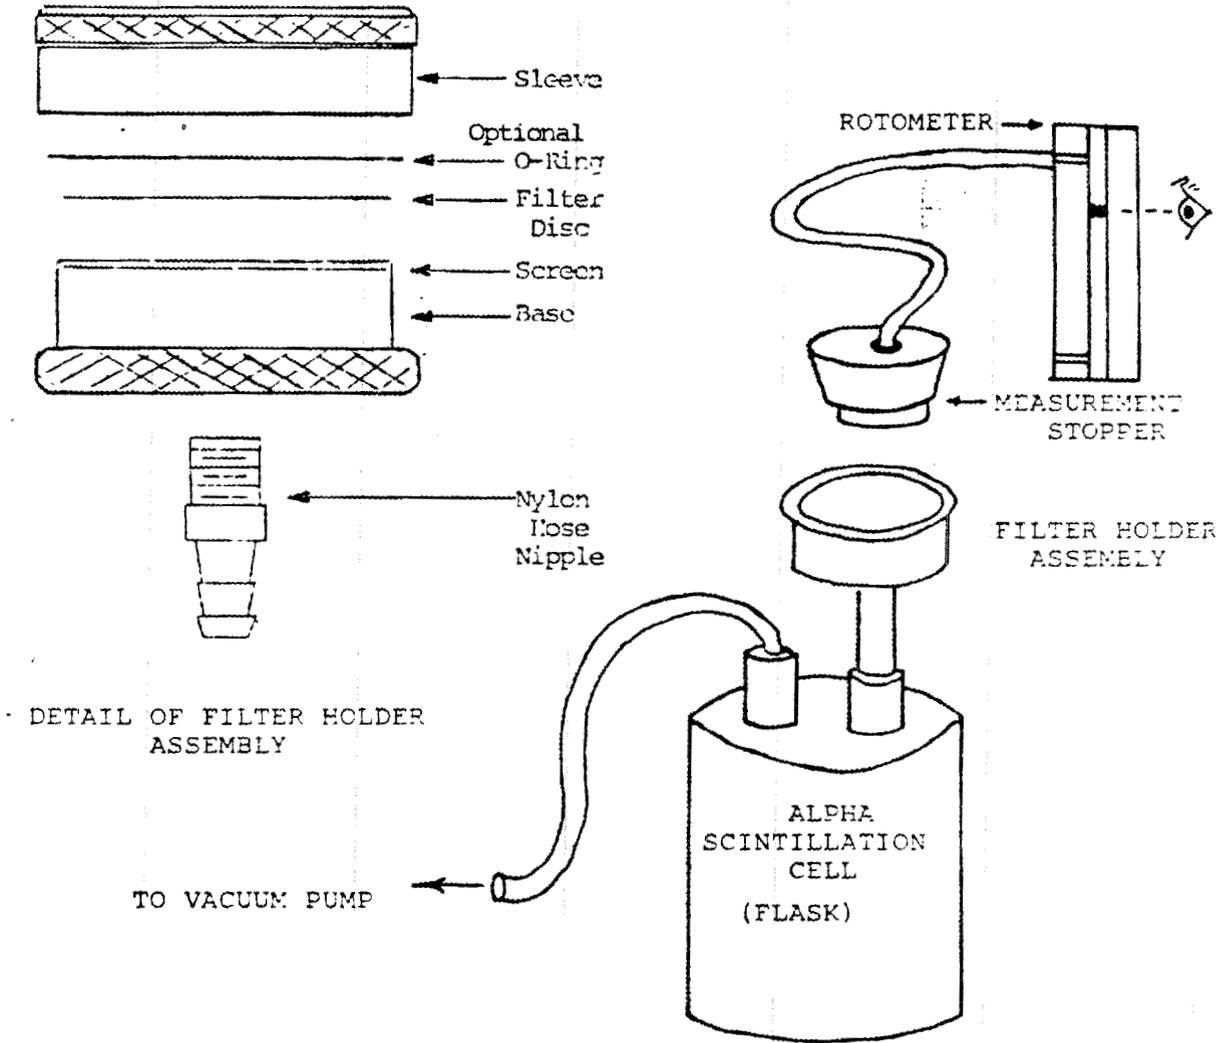

Figure 2 Sampling Configuration for Radon and Radon Daughters

into the front of the filter holder. The rotometer should be held vertically at eye level, and the reading should be made at the center of the ball. If the flow rate exceeds the maximum value of the rotometer, the flow may be reduced by use of a needle valve at the pump. When making this measurement, the stopper should be inserted in the filter before the pump is turned on, and the pump should be run only long enough to obtain the rotometer reading, in order to minimize the particulate accumulation on the filter surface prior to the actual sampling period. Record the rotometer reading on the data form. Once that has been done, the stopper should be removed and the system is now ready for sampling.

5. Remove the stopwatch from the monitoring kit, turn it on, and reset it to zero. Also note the exact time of day that the sampling began, using a watch or other convenient means. When everything is ready, start the stopwatch and the pump simultaneously.

Note: It has been found very useful to start the sample on some even minute according to the monitor's wristwatch. In this way, the sampling/counting sequence can be maintained, even if the stopwatch should malfunction. The time of day is also necessary for the computation of the delay between the sample time and the cell count time.

6. At exactly 5 minutes elapsed time, turn the pump off. Reconnect the stopper and rotometer to the front of the filter holder assembly as in step 4 and turn the pump on only long enough to obtain a final rotometer reading. Record the final rotometer reading on the data form. Disconnect the fittings from the cell, and set the cell aside for later evaluation. Carefully open the filter holder assembly and remove the filter, using the tweezers provided in the kit. Place the filter, with the collection side down, into one of scintillator trays in preparation for counting.

Evaluation of the Radon Daughter Sample

1. Assure that the counting system (EDA Instruments, Inc. model RDA-200) has been checked and found operational, and that a 5-minute filtered grab sample has been properly acquired.
2. Turn the counting system "OFF," open the counting chamber, and remove any scintillator trays or cells from the chamber. Place the scintillator tray, containing the filter to be evaluated, into the counting chamber after removing the protective plastic cap from the tray (if necessary). Reclose the counting chamber with the flat chamber cap. Set the "TIME (MIN)" selector to "10" (for a 10-minute count) and turn the "POWER" switch to "INT." Wait at least two minutes for any residual light activation to die away.
3. At any time between 40 and 90 minutes after the start of sampling, press the "START" button to initiate the count. Enter the actual count start time on the data form (or record the delay time from the

stopwatch). If necessary, calculate the delay from the start of sampling to the start of counting, in minutes, and record it on the data form. Note that it is most convenient to begin the count on an even minute after sampling.

4. When the count is complete, record the total sample counts and the count time (10 minutes) on the data form. The "POWER" switch should be turned to "OFF" and the scintillator tray and sample removed from the counting chamber. The system is now ready to receive the next sample.
5. Calculate the actual flowrate, in liters per minute, from the relation:

$$\text{Flowrate} = (\text{Roto Rdg}) \times (\text{CF}) \times \sqrt{29.92/\text{Bar. Press.}}$$

where: Roto Rdg is the rotometer reading
CF is the correction factor for the rotometer, noted on the calibration sticker on the side of the rotometer.
Bar. Press. is the uncorrected local barometric pressure, obtained from the altimeter/barometer in the kit

Record the actual flowrate on the data form.

6. Calculate the counting efficiency of the counting system from the relation:

$$\text{Eff.} = \frac{\text{cpm of check source}}{\text{dpm of check source}}$$

where: cpm is the count rate of the standardized, electroplated alpha source measured during system checkout
dpm is the true disintegration rate of the alpha source, noted on its storage container

Record the efficiency on the data form.

7. Calculate the radon daughter concentration, in units of working level, from the relation:

$$\text{WL} = \frac{\text{sample cpm} - \text{bkg cpm}}{K \times \text{Eff.} \times \text{Sample length (min.)} \times \text{Flowrate}}$$

where: sample cpm is the count rate of the sample
bkg cpm is the background count rate, obtained during checkout
K is the Kusnetz factor from Table 1, based on the delay period, in minutes, from the end of sampling to the mid-point of the count period
Eff. is the system counting efficiency (calculated above)
Sample length is 5 minutes
Flowrate is as calculated above

Record the WL on the data form.

Evaluation of the Radon Sample

1. Assure that the counting system (EDA Instruments, Inc. model RDA-200) has been checked and found operational, and that at least 4 hours have elapsed since the alpha scintillation cell was filled.
2. Turn the counting system "OFF," open the counting chamber, and remove any scintillator trays or cells from the chamber. Place the cell to be evaluated into the chamber, window side down, after removing the protective plastic cap. Reclose the counting chamber with the extended chamber cap. Set the "TIME (MIN)" selector to 10 minutes (for a 10-minute count) and turn the "POWER" switch to "INT." Wait at least 2 minutes for any residual light activation to die away.
3. Press the "START" button to initiate the count, and note the date and time of the count on the data form.
4. When the count is complete, record the count on the data form and repeat steps 3 and 4 until three 10-minute counts have been recorded. Alternatively, one or more 30-minute counts may suffice for this.
5. Turn the counting system "OFF" and remove the cell from the counting chamber. The system is now ready to receive the next sample.
6. Calculate the number of hours of decay of the sample, from sample collection time to the mid-point of the counting period, and record it on the data form. Calculate the average of three sample counts and record it also.
7. Calculate the radon concentration, in units of picocuries per liter, from the relation:

$$\text{Radon pCi/l} = \frac{\text{sample cpm} - \text{bkg cpm}}{\text{CF} \times \text{Flask Volume (l)} \times \text{decay factor}}$$

where: sample cpm is the average count rate of the sample
bkg cpm is the cell background count rate
CF is the average cell/system counting efficiency, in units of cpm/pCi, obtained from the most recent calibration (typically 3-4)
Flask Volume is 0.16 liter (average for model RDX-013 cells)
decay factor is based on the time between sample collection and the mid-point of the counting period, taken from the table on the data form, or calculated by $e^{-0.00756t}$, where t is the decay time in hours

Record the radon concentration on the data form.

8. Calculate the working level ratio, often called the "percent equilibrium," as follows:

$$\% \text{ Equil} = \frac{(\text{WL}) \times 10,000}{\text{Radon pCi/l}}$$

where: WL and Radon pCi/l are as calculated previously

Record the equilibrium on the data form.

PROCEDURE FOR ACQUISITION AND EVALUATION
OF SHORT-TERM RADON AND RADON DAUGHTER SAMPLESPurpose and Principles of Operation

Short-term or "grab" samples are used to determine the concentrations of radon (Rn-222) gas and radon daughter products in ambient air at a single point in time. By appropriately controlling the environment in which the samples are taken, these instantaneous results are often used to estimate long-term averages, though that is beyond the scope of this procedure. The following describes the acquisition and evaluation of grab samples of radon and/or radon daughters in ambient air using the monitoring kit assembled by ORP-LVF. The contents of the kit are listed in Appendix 1.

Grab sampling for radon and/or radon daughters basically involves the acquisition of a measured volume of air. While the two quantities are measured separately, both types of samples may be acquired simultaneously for convenience. For the radon daughter sample, a measured volume of air is drawn through a membrane filter (Millipore type HA, 0.45-micron pore size, or equivalent). An air pump capable of drawing from 1 to 10 liters per minute is used for the sampling. The filter is subsequently evaluated by alpha scintillation counting the radioactive decay of the particulate radon daughters. In this procedure the Kusnetz Technique (ANSI73) is preferred, but other techniques such as those developed by Tsvoglou (Th70, 71), or Rolle (Ro72) can also be used. In the Kusnetz technique, the filter is counted at any time during a period from 40 to 90 minutes after sampling. The radon daughter concentration, expressed in units of working level (WL), can be calculated from the count rate, the system counting efficiency, the air sampling rate and duration of sampling, and a correction factor for the delay time between the end of the sampling period and the mid-point of the counting period.

The concentration of radon gas is determined using an alpha scintillation cell, similar to the design of Lucas (Lu57), into which a known volume of filtered air is drawn. After a waiting period of at least 4 hours, during which the radon daughters grow into secular equilibrium with the radon, the cell is evaluated by counting the alpha scintillation events. The radon concentration is calculated from the count rate, the predetermined system counting efficiency, the cell volume, and the correction factor for radioactive decay between the times of sampling and counting.

There are four distinct, sequential tasks used to obtain simultaneous "grab" samples of radon gas and its particulate daughters. First, the counting system is standardized by making background counts, followed by counts of the standard alpha scintillation cell (provided with each counting system) and an electroplated disk source of known alpha emission activity. Second, the sample is acquired by connecting the filter holder, scintillation

cell, and air pump in series. Third, the filter is evaluated to determine the radon daughter concentration by the Kusnetz technique. Finally, the alpha scintillation cell is evaluated to determine the radon concentration.

Counting System Checkout Procedures

1. Remove the counting system (EDA Instruments, Inc., model RDA-200) from the carrying case, set it upright on a convenient surface, and turn the main power switch to "INT" (internal battery power). The "LIGHT" warning flag will show red when the instrument is first turned on, but should disappear when sampling is initiated. If it does not disappear, check for light leaks in the counting chamber. Set the "TIME (MIN)" selector to "10" (for a 10-minute count) and depress the "SAMPLE" push-button while observing the "BATT" (battery) warning flag. If the flag shows red, even momentarily, replace the batteries according to instructions in the RDA-200 Operation Manual. Check to see that the "RA-AM" switch is always in the "RA" position.
2. Turn the "POWER" switch to "OFF," open the counting chamber, and remove the standard test cell (normally stored in the chamber when the instrument is not in use). Record the serial number of the cell and the standard count rate in the "Comments" section of the data form (see example, Figure 1). Place the cell into the counting chamber with the window side inward and reclose the counting chamber with the flat chamber cap and threaded ring. Wait at least 2 minutes for any residual light activation to die away, turn the "POWER" switch to "INT," press the "SAMPLE" button, and record the accumulated counts after 10 minutes in the "Comments" section of the data form. Repeat the count, and record. (Note: The red indicator light located beneath the "START" button will blink continuously during the counting period, but will go out when the count is complete. The numeric, 5-digit display will appear when "SAMPLE" is depressed, but the 4 most significant digits will disappear after a few seconds in order to conserve battery life; to read the full display at any time, merely press the "DISPLAY" button).
3. Turn the "POWER" switch to "OFF," open the counting chamber and remove the test cell, and select a scintillator tray from the kit. Remove the black plastic cap from the scintillator tray (if present), carefully place a clean filter paper into the tray (using tweezers to handle the filter), and insert the scintillator tray into the counting chamber. Replace the flat chamber cap and threaded retaining ring, wait at least 2 minutes, and push "START" for a 10-minute background count (this count will be used as the background count for subsequent filter counts for radon daughter measurements). Record the background count in the appropriate block on the data form. Repeat the count, and record.

4. Repeat step 3, using the standardized electroplated disk alpha source in place of the filter paper, to obtain two 10-minute counts for use in calculating the counting system efficiency.
5. Repeat step 3 for each alpha scintillation cell which will be used to make field measurements, in order to obtain the background count rate for each cell. Note that the extender cap for the counting chamber is required for counting cells, in place of the flat cap, and that 30-minute counts for cell background are preferable to 10-minute counts whenever possible. Record the cell (or flask) background counts and count times in the appropriate block on the data form.

Note on alpha scintillation cell preparation: each alpha scintillation cell should be evacuated (using the hand vacuum pump in the monitoring kit or some other appropriate vacuum source to remove the current radon sample) at least 4 hours before commencing the next background count, to allow any residual radon daughter activity to decay away. For measurements of radon in the range commonly found in residences (about 1-10 pCi/l), the background for any cell should not exceed 1 cpm, although higher background count rates may be tolerable for higher expected radon concentrations. If the background is excessive, the cell should be re-evacuated or purged with aged air (or dry nitrogen) and allowed to stand 2-4 hours before re-evaluating the background count rate.

Sample Acquisition

1. Enter the owner's name of the location to be sampled, the address, survey date, and your name (as surveyor) in the appropriate spaces at the top of the data form. Use one form for each structure surveyed, and additional forms as required. Also enter the uncorrected barometric pressure, obtained from the altimeter/barometer in the kit, in the appropriate space on the data form.
2. The pump (Staplex model BN rechargeable type or equal) should be fully charged for proper operation. Do not operate the pump while it is connected to 115V ac power, as damage may result. Four to eight hours of charging is usually sufficient for normal operation.
3. Connect the pump, alpha scintillation cell, and the filter holder assembly (containing an unused membrane filter, Millipore type HA, 0.45-micron pore size, 25-mm diameter) as shown in Figure 2. Connections to the cell are made with male Swagelok quick-disconnect fittings which must be pressed firmly into the female connector until a distinct "click" is heard. All other fittings should be checked to assure they are gas-tight. Record the sample location, pump number, flask or cell number, rotometer number, and counter serial number on the data form.
4. Using the rotometer and the specially modified rubber stopper provided in the monitoring kit, measure the initial air flow rate through the sampling train by pressing the rubber stopper firmly
